We use firm-level panel data for the manufacturing sector in four African countries to investigate whether exporting impacts on efficiency, and whether efficient firms self-select into the export market. Based on simultaneous estimation of a production function and an export regression, our preferred results indicate significant efficiency gains from exporting, which can be interpreted as learning by exporting. We show that modelling unobserved heterogeneity by a flexible approach is important for deriving this conclusion. A policy implication of our results is that Africa would gain from orientating its manufacturing sector towards exporting.

I. INTRODUCTION

It is often argued that trade liberalisation and an export-oriented strategy increase efficiency at company level [Krugman, 1987; Rodrik, 1988, 1991; Grossman and Helpman, 1991]. However, although this is supported by some evidence describing the association between exporting activities and efficiency [Nishimizu and Page, 1982; Haddad, 1993; Harrison, 1994; Aw and Hwang, 1995], there is as yet little systematic evidence that exporting *causes* efficiency gains. Indeed, causality may run in the other direction: efficient firms may self-select into the export market.

One of the first studies that analysed the causal relationship between exporting and productivity at company level was on the US economy [Bernard and Jensen, 1995, 1999a, 1999b]. These authors find little evidence of any learning-by-exporting effect. However, since the US has the largest, most competitive and most technologically advanced economy, it is the least likely to be characterised by efficiency benefits of exporting. There is now a number of studies examining the link between exporting and productivity on countries other than the USA, see Tybout and Westbrook [1995] on Mexico; Clerides *et al.* [1998; henceforth CLT] on Mexico, Colombia and Morocco; Kraay [1999] on China; Aw *et al.* [2000] on the Republic of Korea and Taiwan; Söderbom and Teal [2000] on Ghana; Isgut [2001] on Colombia; and Fafchamps *et al.* [2002] on Morocco. On balance, there is little evidence in these studies that firms improve their efficiency as a result of a learning-by-exporting process. A common conclusion is that efficient firms self-select into the export market.¹

In this paper we provide across-country evidence on this issue for sub-Saharan Africa. Our study is based on panel data on manufacturing firms in Cameroon, Ghana, Kenya and Zimbabwe. These countries have had high trade restrictions in the past and are widely regarded as technologically backward (see Bigsten *et al.* [1999] for a review of the policy environments in the four countries). In such economies the potential gains from exporting are large. Exporting offers the maximum scope for the increased discipline of competition, and contact with foreign customers provides the maximum scope for learning opportunities. Thus, if exporting induces efficiency in any environment, it should do so in these economies.² From a policy perspective, whether or not firms learn from exporting is an important issue. Africa's domestic markets for manufactures are so small that if African countries are to industrialise, it will have to be through exports. At present there is a substantial competitiveness gap, and under learning-by-exporting such a gap can be reduced endogenously through increased international trade.

Several methodological problems arise when attempting to test for, and distinguish between, learning-by-exporting and self-selection effects. Our

approach, which is similar to that of CLT, involves simultaneous estimation of a dynamic production function and a dynamic discrete choice model for the decision to export, where we allow for causality running both from efficiency to exporting and from exporting to efficiency. This strategy enables us to control for unobserved heterogeneity in the form of firm specific effects that are correlated across the two equations. In addition we consider an instrumental variables estimator in order to see if our results are robust. A methodological issue to which we devote considerable attention is the manner in which this unobserved heterogeneity should be modelled. We show that alternative models can give radically different results.

The remainder of the paper is organized as follows. Section II presents our empirical framework and the econometric methods. Section III provides an overview of the data. Section IV reports econometric results analysing the relationship between company-level efficiency and export history. Section V concludes.

II. EMPIRICAL FRAMEWORK

We analyse the link between exporting and efficiency using a production function approach. Our baseline production function is taken to be Cobb-Douglas, modelling output as a function of capital, labour and intermediate inputs:

$$y_{it} = \lambda y_{i,t-1} + (1 - \lambda) \{ \beta_n n_{it} + \beta_k k_{it} + \beta_m m_{it} + \beta_e e_{it} \} + \log A_{it} + \eta_{it},$$

where y_{it} is log output, n_{it} is log employment, k_{it} is log capital stock, m_{it} is log raw material, e_{it} is log indirect costs (for instance electricity, water, transport etc.), A_{it} is total factor productivity, or efficiency, λ and β denote parameters to be estimated, η_{it} is a residual, assumed serially uncorrelated, that captures efficiency shocks and $i = 1, 2, \dots, N$ and $t = 1, 2, \dots, T$ are company and time indices, respectively. The model allows for dynamics in the form of a lagged dependent variable (see Nickell [1996] for a similar specification). One potential reason for dynamics of this form is that whenever factors of production are changed it may take time for output to reach its new long-run level. The inclusion of a lagged dependent variable also makes serial correlation of the residual less likely. In the empirical analysis we consider the effects of allowing for a more flexible specification than Cobb-Douglas, as well as modelling value-added rather than gross output.³

Based on the learning-by-exporting idea, we hypothesise that A_{it} depends on exporting and, as learning is unlikely to be instantaneous, that this effect operates with a one-period lag.⁴ We allow for heterogeneity in A_{it} by including dummy variables for country, industry, time and firm status

(ownership), summarised by the vector c_{it} , and for unobserved heterogeneity in the form of firm-specific effects, denoted μ_i . We hence write A_{it} in logarithmic form as

$$\log A_{it} = \delta \cdot \text{exports}_{i,t-1} + c_{it} + \mu_i,$$

where *exports* is a dummy variable equal to one if there is some exporting and zero if there is not. Substituting this expression into the production function yields,

$$y_{it} = \lambda y_{i,t-1} + (1 - \lambda) \{ \beta_n n_{it} + \beta_k k_{it} + \beta_m m_{it} + \beta_e e_{it} \} + \delta \cdot \text{exports}_{i,t-1} + c_{it} + \mu_i + \eta_{it}, \quad (1)$$

which forms the basis for our econometric test for learning effects due to exporting.

A simple empirical approach would be to estimate (1) using for instance OLS or the standard panel GLS ('random effects') estimator. Unfortunately this approach is likely to yield misleading results if exports and productivity are correlated for reasons other than causality running from exports to efficiency. This is emphasised by CLT, arguing that the positive association between export status and productivity can be due to the self-selection of the relatively more efficient firms into foreign markets, rather than learning. In the econometric analysis CLT deal with this problem by formulating a model for export participation in which they allow for unobserved firm effects that are potentially correlated with the unobserved company effects in the productivity equation. We use a similar approach in this paper.

We assume export participation to depend on previous export participation, company size, labour productivity, capital intensity, raw material per employee and indirect costs per employee and a vector of control variables d_{it} . Previous export participation is included in the model to control for fixed costs associated with entering the export market [Roberts and Tybout, 1997]. Similarly company size, measured here as the natural logarithm of employment, has a fixed costs interpretation in that exporting typically is associated with costs too large for small firms to incur; for instance, it may be necessary for the exporting firm to set up a marketing department to investigate marketing channels, meet export orders etc. Labour productivity, capital intensity, raw material per employee and indirect costs per employee are included in the model to capture a potential self-selection process noted by CLT, by which certain firms choose to export because they are relatively efficient. Given that we control for the factor inputs in the production function (normalised by employment), the coefficient on the labour productivity term is a sufficient statistic for efficiency. Thus we represent efficiency by observables rather than relying

on a two-stage procedure where efficiency initially is estimated and then used as a regressor in the export equation.

Because our exports variable is binary we employ a latent variable formulation and, taking the above into account, write the exports equation as

$$\begin{aligned} \text{exports}_{it}^* = & \gamma \cdot \text{exports}_{i,t-1} + \theta_n \cdot n_{it} + \theta_y (y_{i,t-1} - n_{i,t-1}) + \\ & \theta_k \cdot (k_{i,t-1} - n_{i,t-1}) + \theta_m \cdot (m_{i,t-1} - n_{i,t-1}) + \\ & \theta_e \cdot (e_{i,t-1} - n_{i,t-1}) + d_{it} + \psi_i + \omega_{it}, \end{aligned} \quad (2)$$

where we observe $\text{exports}_{is} = 1$ if $\text{exports}_{is}^* \geq 0$ otherwise zero. Here, γ and θ denote parameters to be estimated, ψ_i is an unobserved firm-specific time invariant effect affecting the decision to export and ω_{it} is a homoskedastic, serially uncorrelated and normally distributed residual whose variance we normalise to one. These assumptions about the residual imply that we can estimate the parameters of interest using a dynamic probit model. We assume that self-selection into exporting operates with a one-period lag, reflected in (2) by the $t-1$ subscripts on labour productivity, capital, raw material and indirect costs. The coefficient θ_y thus represents the self-selection effect.

Estimation of (1)-(2) will shed light on, *inter alia*,

- i) if there is support for the learning-by-exporting hypothesis, that is that firms improve efficiency as a result of exporting (in which case δ would be positive);
- ii) if there is support for self-selection-into-exporting, that is that efficient firms become exporters (in which case θ_y would be positive);
- iii) if there are fixed costs associated with exporting, so that firms tend to continue exporting once they have entered the international market (in which case γ would be positive; Roberts and Tybout [1997]).

Because the models contain lagged dependent variables it is crucial to control for heterogeneity between firms or we would expect the estimates to be upward biased, reflecting ‘spurious’ state dependence [Heckman, 1981a, 1981b]. While the vectors of control variables c_{it} and d_{it} control for heterogeneity in certain observed variables, presence of unobserved heterogeneity in the form of the company specific effects μ_i and ψ_i presents us with some econometric problems. These are discussed next.

Estimation

In estimating (1)-(2) we mainly rely on maximum likelihood (ML) methods, although we also consider generalised methods of moments (GMM)

[Hansen, 1982] estimator. We use three distinct ML models, one of which assumes that there is no unobserved heterogeneity in the form of firm specific effects, while the remaining two assume that μ_i and ψ_i can be modelled by means of a random effects approach. Equations (1)–(2) contain four random terms, namely μ_i , η_{it} , ψ_i and ω_{it} . In our most general ML model we assume that

$$(\mu_i, \psi_i, \eta_{it}, \omega_{it}) \sim G(\zeta, \Omega) \tag{3}$$

where G is some distribution function, $\zeta = (\zeta_\mu, \zeta_\psi, 0, 0)$, and

$$\Omega = \begin{vmatrix} \sigma_\mu^2 & & & \\ \sigma_{\mu\psi} & \sigma_\psi^2 & & \\ 0 & 0 & \sigma_\eta^2 & \\ 0 & 0 & \sigma_{\eta\omega} & \sigma_\omega^2 \end{vmatrix} = \begin{vmatrix} \sigma_\mu^2 & & & \\ \rho_{\mu\psi}\sigma_\mu\sigma_\psi & \sigma_\psi^2 & & \\ 0 & 0 & \sigma_\eta^2 & \\ 0 & 0 & \rho_{\eta\omega}\sigma_\eta & 1 \end{vmatrix}, \tag{4}$$

where $\rho_{\mu\psi}$ and $\rho_{\eta\omega}$ denote the correlation between μ and ψ , and between η and ω , respectively. Thus the transitory errors η_{it} and ω_{it} are taken to be uncorrelated with the permanent effects μ_i and ψ_i , an assumption we make for computational reasons. Throughout the analysis we assume that η_{it} and ω_{it} follow a bivariate normal distribution.

Our simplest model imposes the restriction $\sigma_\eta^2 = \sigma_\psi^2 = \rho_{\mu\psi} = 0$, which amounts to assuming that there is no unobserved heterogeneity in the form of firm specific effects. In this special case the likelihood function can be written ignoring the panel nature of the data altogether. While this model is straightforward to estimate, the presence of dynamic terms in the regression means that consistency of the estimates hinges crucially on the absence of unobserved heterogeneity. Even though the model thus is rather restrictive, it is useful as a benchmark. The likelihood function is shown in the Appendix, Part A.

The second model is similar to that used by CLT in assuming that μ_i and ψ_i follow a bivariate normal distribution.⁵ In this case the likelihood function involves multiple integrals which makes computation rather more difficult than for our first model. Following CLT we deal with this by integrating out the random effects μ_i and ψ_i using a bivariate Gaussian quadrature. Details on this procedure, and the likelihood function, are given in Part B of the Appendix. In the remainder of the paper we refer to this model as the CLT model.

Although the CLT model is attractive in that it allows for unobserved firm effects that are correlated across the two equations, the distributional assumptions about the error structure are potentially restrictive. In our third

ML model we relax the assumption that μ_i and ψ_i are normally distributed, and follow Heckman and Singer [1984] in adopting a non-parametric strategy for characterising the distribution of the random effects. Specifically, we assume that the bivariate distribution of μ_i and ψ_i can be approximated by a discrete multinomial distribution with $Q \times R$ points of support:

$$\Pr(\mu = \mu_q, \psi = \psi_r) = P_{qr}, \quad q = 1, 2, \dots, Q; r = 1, 2, \dots, R;$$

$$\sum_{q=1}^Q \sum_{r=1}^R P_{qr} = 1,$$

where the μ_q , ψ_r and P_{qr} are parameters to be estimated.⁶ Hence, the estimated support points determine where the observations are positioned, P_{qr} and indicate the proportion of the observations found at each particular point. This model is flexible and several restrictions inherent in the CLT model (for instance symmetric distribution of heterogeneity) are avoided.⁷ In estimating the model, one important issue refers to the number of support points, Q and R . In fact, there are no well-established criteria for determining the number of support points in models like these (see for instance Heckman and Walker [1990]), so we follow standard practice and increase Q and R until there are only marginal improvements in the log likelihood value.⁸ Usually, the number of support points is small; indeed, for $Q = 1, R = 1$ unobserved heterogeneity is absent and the production function and the exports equation are independent, implying that our first model discussed above may be used to estimate the parameters of interest. The likelihood function is given in the Appendix, Part C. In the remainder of the paper we refer to this model as the NPML model.

In forming the likelihood underlying the CLT and NPML models, we have to recognise the presence of lagged dependent variables among the explanatory variables. This creates an initial conditions problem both in the production function and in the export probit, in that $exports_{i0}$ and y_{i0} will be correlated with the firm specific effects if $exports_{i0}$ and y_{i0} have been determined by the same model as that determining productivity and exports from $t = 1$ and onwards.⁹ Neglecting the initial conditions problem leads to inconsistent parameter estimates unless T is large. Following Heckman [1981a, 1981b] we approach this problem by specifying models for the initial conditions $exports_{i0}$ and y_{i0} , allowing these variables to depend on the random effects μ_i and ψ_i by means of a factor loading approach (see Appendix, Part B). The parameters of the initial conditions models are then estimated jointly with the other parameters. CLT use a similar approach.

All ML models discussed above assume that all explanatory variables except $exports_{i,t-1}$ and $(y_{i,t-1} - n_{i,t-1})$ are uncorrelated both with the firm

specific effects and the transitory errors. This assumption is made for computational reasons, and it is of obvious interest to investigate how strong an assumption this is. While it would be possible to relax the exogeneity assumption for all variables within the ML framework, estimation would have to proceed in one step to avoid a substantial efficiency loss [Mroz, 1999]. One-step estimation involves adding additional equations to the system – one for each endogenous variable – and then estimating all equations simultaneously. Unfortunately this becomes increasingly computationally intractable as the number of endogenous variables grows. Instead, we estimate the production function using instrumental variables in a GMM framework. This is a similar strategy to that adopted by CLT.

III. DATA AND SUMMARY STATISTICS

Our data are for manufacturing firms in four African countries – Cameroon, Kenya, Ghana and Zimbabwe. The data were collected during the period 1992 to 1995 as part of the Regional Program on Enterprise Development (RPED) coordinated by the World Bank. In each country, over a period of three years, a panel of companies in the manufacturing sector was surveyed and information was gathered on a variety of issues, including outputs and resource use. The periods covered by the surveys were as follows: for Kenya, 1992 to 1994; for Ghana, 1991 to 1993; for Zimbabwe, 1992 to 1994; and for Cameroon, 1992/93 to 1994/95. All the countries faced problems in their macroeconomic environments that had a significant impact on manufacturing sector performance. They had all adopted import substitution development policies from independence through the late 1970s. In the mid-to-late 1980s, they had all introduced ‘structural adjustment’ programmes with the support of the World Bank and other aid organisations, with emphasis on macroeconomic reforms, trade liberalisation and privatisation. The scope and success of these programmes varied. For a discussion of policy in the four countries see Bigsten *et al.* [1999, 2001].

Throughout the paper we use the balanced panel of those firms for which observations exist for all three survey years, because this is the minimum time period necessary to control for unobserved company effects in the econometric analysis.¹⁰ We correct for changes in exchange rates during the sampling years, given that devaluation would make an exporting firm to appear more productive as the value of its output is valued more highly in terms of local currency, which could induce spurious correlation. To this end we use firm-specific deflators based on export share-weighted averages of the domestic and international prices. In the same manner, inputs are

deflated using import shares.¹¹ Of course, this is unlikely to yield perfect deflators but it is difficult to do better given the data available.

Table 1 shows summary statistics on the estimation sample, where the sample is split by initial export status. Because our regressions include lags we lose one wave of the data, hence only two years of data are being used here. About 29 per cent (85 out of a total of 289 firms) of the firms observed at $t = 0$ are exporters, and within this group of initial exporters the proportion of exporters in the consecutive two years is about 85 per cent. In the group of initial non-exporters, only 8 per cent of the observations record any exporting in the subsequent two years. Hence there is strong persistence in the export data. Further, initial exporters are larger than non-exporters, and exhibit higher labour productivity and higher capital intensity. Sixty-one per cent of the initial exporters are Zimbabwean companies, and 40 per cent of the initial exporters have some foreign ownership. There is no obvious pattern across sectors.

IV. ECONOMETRIC ANALYSIS

Table 2 reports selected estimates for our baseline specification, using the three ML models discussed in Section II. The production function, taken to be Cobb-Douglas, models gross output. Column [1] shows the results for

TABLE 1
SUMMARY STATISTICS, BY INITIAL EXPORT STATUS

	Initial Exports = 0 (Number of firms: 204)			Initial Exports = 1 (Number of firms: 85)		
	Mean	p50	Std. dev.	Mean	p50	Std. dev.
VARIABLE IN $T = 1,2$						
Exports	0.08			0.85

Any state ownership	0.03			0.08		

Note: Variables for which p50 and Std. dev. are not reported are dummy variables.

the simplest model, that is where firm effects are ignored altogether. In the production function all inputs in are significant at the five per cent level or better and sum to 0.85, which, given that the coefficient on the lagged dependent variable is 0.16, implies that long-run constant returns to scale can easily be accepted (test not reported). The estimated coefficient on the lagged export variable is equal to 0.07 and significant at the 5 per cent level, thus suggesting a positive effect of exporting on to efficiency. In the export probit the coefficient on $(y_{t-1} - n_{t-1})$ is positive but small and far from significant. Thus we cannot reject the hypothesis that a change in efficiency at time t has no effect on the export probability at time $t+1$, suggesting that the self-selection mechanism is weak. However $(y_{t-1} - n_{t-1})$ is quite strongly correlated with capital, raw material and indirect costs (all normalised by employment), and a joint test of the hypothesis that the coefficients on these four terms are zero can be rejected at the 10 per cent level (p -value: 0.054). It is thus possible that an increase in efficiency is associated with more intensive utilisation of capital and intermediate inputs in such a way as to mask the direct effect on exporting. The coefficient on lagged export is equal to 2.02 and highly significant, indicating strong persistence in the exporting decision.¹² Of course, given that we do not control for time invariant company effects here, this effect is probably upwardly biased reflecting 'spurious' state dependence [*Heckman, 1981a, 1981b*]. The coefficient on employment is positive and highly significant. The result that contemporaneous exports is affected by lagged exports and size can be interpreted as evidence for fixed costs (see Section II).

Next consider the effects of allowing for unobserved heterogeneity. Column [2] shows the results of the CLT model in which the company effects are taken to follow a bivariate normal distribution. The increase in the log likelihood value compared to Column [1] indicates that this model provides a far better fit to the data than the simpler model. Strikingly, there is now no evidence for learning by exporting, as the coefficient on lagged exports is far from significant and the point estimate is even negative. There is unobserved heterogeneity both in the production function and in the export equation, and the estimate of $\rho_{\mu\psi}$ indicates that the correlation between μ and ψ is equal to 0.33. This suggests that the positive coefficient on the export variable in Column [1] is upwardly biased due to the omission of unobserved heterogeneity, consistent with the argument of CLT. Further, in the export equation the coefficient on lagged exports is now negative but insignificant. The reason is that the estimate of σ_{ψ} , the standard deviation of the random effect ψ_i , is very high indeed. This would imply that the observed persistence in the export data documented in Column [1] is entirely due to unobserved time invariant heterogeneity, and not driven by a causal effect of past on contemporaneous exporting as predicted by the sunk

Log likelihood value	-390.93	-353.57	-332.37
Number of firms	289	289	289

Note: The dependent variable in the production function is the log of gross output. The dependent variable in the export equation is a dummy variable equal to one if the firm exports and zero otherwise. All regressions include dummy variables for country, industry, ownership and time. The numbers in () are *t*-statistics based on asymptotic standard errors. Significance at the 1 per cent, 5 per cent and 10 per cent level is indicated by *, ** and + respectively.

cost model developed by Roberts and Tybout [1997]. In the production function all coefficients on the input factors are significant, and the long-run elasticities sum to 1.03. In the export equation the coefficient on labour productivity is positive but insignificant, providing little evidence for self-selection. Possibly the reason that we fail to obtain a direct self-selection effect is that labour productivity is strongly correlated with the factor input terms, as discussed above. The employment coefficient is positive and highly significant.

The CLT results thus provides no evidence in favour of the learning-by-exporting hypothesis. Consider now the effect of relaxing the assumption that μ and ψ are normally distributed. Column [3] reports NPML estimates where the bivariate distribution of μ and ψ is taken to be discrete with 3×3 points of support.¹³ The resulting log likelihood value is 21 units higher than in the CLT model, indicating that the NPML model provides a much better fit to the data. Several results are worth noting. First, the estimated coefficient on lagged exports is equal to 0.07 and significant at the 5 per cent level. In fact, the point estimate is almost identical to the result shown in Column [1]. Thus we can now reject the null hypothesis that exporting has no effect on efficiency. The lower part of Table 2 shows that the estimated standard deviations of μ and ψ are rather much smaller than in the CLT model, and there is no evidence that μ and ψ are correlated. It is therefore not surprising that some of the coefficients in the production function and the export equation are rather different. Further, in the exports equation the coefficient on lagged exports is now significant and much higher than in the CLT model.¹⁴ Finally, it is noted that the long-run elasticities in the production function sum to 1.02, that in the export equation the coefficient on labour productivity is positive but insignificant, and that the employment coefficient is positive and highly significant.

Allowing for a more flexible form of unobserved heterogeneity than that based on the bivariate normal distribution has led to radically different estimates of the associated moments, which have far-reaching implications for the estimates of the coefficients of interest. Table 3 shows the NPML estimate of the joint probability distribution of μ and ψ . Clearly the distribution is quite asymmetrical, which suggests that joint normality will be a restrictive assumption for these data. We now probe the data further, in order to investigate if the learning-by-exporting result obtained in Table 2, Column [3], is robust to alternative specifications. We begin by considering a more flexible functional form for the production function. One flexible form that has been used extensively in studies estimating cost and production functions is the second-order transcendental logarithmic ('translog') production function [Christensen *et al.*, 1971; Berndt and Christensen, 1973]. This is a generalisation of the Cobb-Douglas model that

TABLE 3

	μ_3 : 0.361	0.000	0.000	0.006	0.006
	$f_\psi(\psi)$	0.626	0.352	0.023	

Note: The table shows the estimated probability distribution based on the model reported in Table 2, Column [3]. The positions of the random effects are indicated by $\mu_1, \dots, \mu_3, \psi_1, \dots, \psi_3$. Four of the estimated joint probabilities tended to zero when estimated freely. To obtain a non-singular Hessian we consequently imposed zero values on these probabilities. $f_\mu(\mu)$ and $f_\psi(\psi)$ indicate the marginal probabilities.

includes squared and interacted terms of the factor inputs (in natural logarithms), in addition to the levels terms. Output elasticities hence vary with the levels of the inputs, and to facilitate interpretation of the results we therefore report elasticities evaluated at sample means of the regressors. The non-linear form of the translog model also implies that the regularity conditions of the production function, notably monotonicity and quasi-concavity, will have to be investigated at each data point.¹⁵

In Table 4, Columns [1]–[2], we report results where the production function is assumed to be second-order translog, for the CLT and the NPML specifications. In both cases there is a significant increase in the log likelihood value, suggesting that the translog specification provides a better approximation of the technology than the Cobb-Douglas model.¹⁶ Evaluated at sample means, the estimated elasticities of the inputs are nevertheless similar to the Cobb-Douglas coefficients. As for the effect of exporting on efficiency, the results of the CLT and NPML models are very similar to their Cobb-Douglas counterparts. In the CLT model the coefficient on exporting is negative and insignificant, while in the NPML model the coefficient is about 0.07 and statistically significant at the 5 per cent level. Again, the log likelihood value of the NPML model is much higher than that of the CLT model suggesting that the former provides a better fit to the data. Thus, while the translog specification may seem preferable to the Cobb-Douglas model, the effect of exporting on efficiency appears not to be sensitive to the functional form of the production function. In the export equation there is evidence for a strong size effect in both specifications, and for persistence in the NPML model. For both models the estimated distribution of the random effects is similar to the results in Table 3.

Thus far the production function has modelled gross output as a function of capital, labour and intermediate inputs. In Table 4, Columns [3]–[5], we report production functions that model value-added, defined as the value of

Note: In Columns [1]–[2] the dependent variable in the production function is the log of gross output and in Columns [3]–[5] it is the log of value-added. The dependent variable in the export equation is a dummy variable equal to one if the firm exports and zero otherwise. All regressions include dummy variables for country, industry, ownership and time. The numbers in () are *t*-statistics based on asymptotic standard errors. Significance at the 1 per cent, 5 per cent and 10 per cent level is indicated by *, ** and + respectively.

[§]For the translog production function, the reported numbers associated with the inputs k_t , n_t , m_t , e_t are marginal effects. These are functions of the inputs, and have therefore been evaluated at sample means. The standard errors and *t*-values have also been evaluated at sample means.

output minus the value of raw materials and indirect costs, with capital and labour as the factor inputs. As expected, the production function coefficients are much larger in magnitude than in the gross output production function.¹⁷ The model without company effects yields a positive and significant coefficient on the exports variable, while the CLT model again yields a negative and insignificant coefficient, providing no evidence for learning. In estimating the NPML model the variance of μ systematically tended to zero despite using more than 100 different vectors of start values, and we therefore imposed zero variance in this model. The NPML parameter estimates of the production function are similar in magnitude to those shown in Column [3]. Most notably, the coefficient on the export variable is positive and significant at the 5 per cent level. Thus the pattern is the same as that documented earlier, in that imposing bivariate normality on these data dramatically affects the coefficient on the export dummy. Again the NPML model yields the highest log likelihood value. In the export equation there is a strong size effect in all specifications, while the evidence for a self-selection effect is weak except in the model without firm effects.¹⁸

In the CLT and NPML specifications reported above we allowed for correlation between the exports variable and the firm specific effect. Although we obtained evidence from our preferred model that this correlation is close to zero, it is possible that the results are biased if the

Note: The dependent variable in the production function is the log of gross output. The numbers in () are t -statistics. Significance at the 1 per cent, 5 per cent and 10 per cent level is indicated by *, ** and + respectively. Hypothesis tests are based on robust, finite sample corrected standard errors calculated using the method proposed by Windmeijer [2000].

1. The regression includes a constant. The instrument set consists of a constant, y_{t-2} , k_{t-2} , n_{t-2} , m_{t-2} , e_{t-2} , k_{t-1} , n_{t-1} , m_{t-1} , e_{t-1} , export_{t-1} , k_t , n_t , m_t , e_t .
2. The levels equation includes a constant and dummy variables for country, industry, ownership and time. The instrument set for the levels equation consists of a constant, y_{t-1} , k_{t-1} , n_{t-1} , m_{t-1} , e_{t-1} , export_{t-1} , dummy variables for country, industry, ownership and time. The instrument set for the differenced equation consists of y_{t-2} , k_{t-2} , n_{t-2} , m_{t-2} , e_{t-2} .
3. Tests for the validity of the overidentifying restrictions. Note: d.f. = degrees of freedom; $p = p$ -value.
4. Tests the null hypothesis that: k_{t-1} , n_{t-1} , m_{t-1} , e_{t-1} , k_t , n_t , m_t , e_t , export_{t-1} are orthogonal to the differenced error term and k_t , n_t , m_t , e_t , export_{t-1} are orthogonal to the levels error term. This is done by means of a C-test [Hayashi, 2000: 218–21], computed as the difference between two J statistics: that for the efficient estimator and that for the consistent but inefficient estimator. Note: d.f. = degrees of freedom; $p = p$ -value.

factor inputs are correlated either with the firm specific effect or with the transitory residual. In investigating if this is the case we begin by estimating the production function allowing for fixed company effects that may be correlated with the factor inputs. Because the model contains a lagged dependent variable and the time dimension of our panel is very small, standard within estimation of the model is likely to generate substantial bias of the form identified by Nickell [1981]. An alternative way of estimating the parameters is to eliminate the fixed effects by taking first differences and to use instruments to deal with the problem that $\Delta y_{i,t-1}$ will be correlated with $\Delta \eta_{it}$ as a result [Andersen and Hsiao, 1981; Arellano and Bond, 1991].¹⁹ The first column of Table 5 shows two-step GMM estimates of the Cobb-Douglas output production function in first differences, where the t -statistics are based on robust, finite sample corrected standard errors [Windmeijer, 2000].²⁰ The instrument set is specified in its entirety in the notes to Table 5.

Three results are noted. First, the t -values are much lower than in previous specifications. This is not surprising, given that the first differencing procedure reduces the variation in the explanatory variables. The estimated coefficients on raw materials and indirect inputs are similar to what was obtained in previous specifications, while the employment coefficient is somewhat larger. The capital coefficient is insignificant, which is a similar result to that of, *inter alia*, Mairesse and Hall [1996], Griliches and Mairesse [1997] and Nickell [1996]. A common explanation why controlling for fixed effects in the production function tends to give unsatisfactory estimates of the capital coefficient is that the differencing procedure exacerbates the bias caused by measurement errors [Griliches and Mairesse, 1997]. Second, while the coefficient on exports is no longer significant, the point estimate is equal to 0.10 thus larger than in previous models. This suggests that assuming the factor inputs to be uncorrelated with the firm effect does not yield an upward bias in the estimated exports coefficient. Third, the overidentifying restrictions appear to be valid, as indicated by the Sargan-Hansen test. This suggests that the assumption that the factor inputs dated t and $t-1$ are uncorrelated with $\Delta \eta_{it}$ is not overly restrictive.

Finally we consider the effects of allowing the factor inputs to be correlated both with the firm effect and μ_i with the residual η_{it} . This rules out using factor inputs dated t and $t-1$ as instruments, leaving us only with inputs dated $t-2$. In practice, lagged levels variables often constitute weak instruments for contemporaneous differences, especially when the data are highly persistent which is typically the case for production function variables. Because weak instruments potentially give rise to finite sample bias and poor precision of the estimates, we follow Blundell and Bond

[1998] and form a two-equation system consisting of the differenced equation and the original levels equation (1). This approach, termed system GMM, involves estimating the two equations simultaneously, subject to appropriate cross-equation restrictions that constrain the coefficient vectors in the two equations to be identical. Monte Carlo experiments reported by Blundell and Bond [1998] indicate that the system GMM estimator performs much better than the standard differenced GMM estimator when the data are highly persistent. Blundell and Bond [2000] use system GMM to estimate production function parameters based on US data. Following their approach, we use lagged levels as instruments for contemporaneous differences and lagged differences as instruments for contemporaneous levels (see notes to Table 5).

Two-step system GMM estimates are shown in the second column of Table 5. Despite the system approach we fail to obtain precise estimates of most of the coefficients, the only significant one being that on raw material. Although far from significant, the point estimate of the exports coefficient is 0.064 which is very close indeed to the NPML estimate in Table 2. This suggests that assuming the factor inputs to be exogenous is not overly restrictive. We test formally for exogeneity by means of a C-test [Hayashi, 2000: 218–21], which involves adding to the instrument set variables that we suspect may not be exogenous, and then testing whether the hypothesis that these variables are uncorrelated with the residual can be rejected.²¹ The outcome of this test indicates that exogeneity cannot be rejected at the 10 per cent level of significance.

Summarising, the GMM results indicate that taking the factor inputs to be exogenous, an assumption that underlies the production function specifications in Tables 2 and 4, is not overly restrictive.²² The fact that the standard errors increase when we do not impose exogeneity on the data is to be expected. The point estimates of the exports coefficient are very similar to that of our preferred model, and thus consistent with the learning-by-exporting hypothesis. The evidence also seems quite clear that assuming the random effects to follow a bivariate normal distribution is an incorrect assumption for these data, and that imposing bivariate normality has a considerable effect on some of the parameter estimates.²³ Most notably, under bivariate normality there is no significant exporting effect on productivity. Why is the normality assumption problematic in the current application? In the univariate case there is a fairly large literature discussing parametric assumptions regarding the distribution of unobserved heterogeneity. We are unaware of any paper discussing this issue for bivariate distributions.²⁴ Further inspection of Tables 2 and 4 gives us some clues of the nature of the problem. The CLT exports coefficient in the production function is imprecisely estimated. In Table 2 its 95 per cent

confidence interval ranges between -0.095 and 0.083. Further, the low CLT estimate of the exports coefficient is accompanied by a relatively high estimate of $\rho_{\mu\psi}$, measuring the correlation of the two time invariant random effects. Estimating the CLT model in Table 2 imposing $\rho_{\mu\psi} = 0$ yields a point estimate of the exports coefficient equal to 0.06, which is very similar to the NPML model.²⁵ Hence under bivariate normality we obtain something similar to an identification problem, where it is difficult to distinguish between a causal effect and time invariant heterogeneity. Investigating whether this is a general result for models of this kind is left for future research. What seems clear is that a more flexible characterisation of the distribution of the random effects greatly improves our ability to pin down the parameters of interest in the model.

V. CONCLUSION

In this paper, we have examined two not incompatible explanations for the positive association between export-participation status and productivity: self-selection of the relatively more efficient plants into exporting, and learning by exporting, using panel data on manufacturing firms in four African countries. Our preferred estimates show that, consistent with the learning-by-exporting hypothesis, exporting impacts positively on productivity. This result is not sensitive to the functional form of the production function, and neither is there any evidence that neglected simultaneity is driving the result. There is little direct evidence for self-selection into the export market. However we have noted that this may be due to the co-linearity between some of the regressors in the export probit. The evidence also indicates that past exporters are more likely to remain active in the export market, consistent with the presence of sunk cost of breaking into foreign markets [*Roberts and Tybout, 1997*].

There is strong evidence for unobserved heterogeneity in the data, only detectable with panel data. It is however quite clear that assuming the random effects to follow a bivariate normal distribution is an incorrect assumption. Using a more flexible specification yields an asymmetrical distribution of the firm effects, which is inconsistent with normality. Further, imposing bivariate normality on the data has a considerable effect on some of the parameter estimates. Most notably, under bivariate normality there is no significant exporting effect on productivity. It is noted that CLT obtain a similar result, leading the authors to conclude that ‘the association between exporting and efficiency is most plausibly explained as low-cost producers choosing to become exporters’ [*CLT: 942*]. Had we confined ourselves to the CLT model, our conclusion would probably have been the same.

From a policy perspective, the result that there is learning-by-exporting is an important one. Africa's domestic markets for manufactures are so small that if African countries are to industrialise, it will have to be through exports. Our results provide strong support for the view that learning-by-exporting is possible in Africa. If this is so, Africa has much to gain from orientating its manufacturing sector towards exporting.

NOTES

1. Kraay [1999], however, finds some evidence for learning-by-exporting in Chinese industry, mainly among established exporters.
2. There is, however, a literature which argues that company productivity in Africa can only be increased by interventions aimed at improving skills and the technical capacity of the firms to absorb new technology [Lall, 1990; Pack, 1993]. These authors would argue that such improvements are necessary before firms can become internationally competitive.
3. Value-added production functions appear to be more common in the literature; however research by Basu and Fernald [1995] shows that adopting a value-added production function can yield misleading results if there is imperfect competition or increasing returns to scale.
4. Our sample, described in Section III, consists of three waves of panel data. Given the presence of unobserved firm effects, we cannot allow for a longer lag structure than one period. Because the production function contains a lagged dependent variable, entry into, or exit from, the export market will nevertheless have a dynamic effect in that efficiency will be affected for several subsequent time periods. Hence if, for instance, a firm exits at time t it will experience a gradual decline in its efficiency. In the initial periods after exiting its efficiency will be higher than that of an otherwise identical firm that has never exported, but in the long run the efficiency levels of the two firms will converge to the same level.
5. A similar specification has also been used by Keane *et al.* [1988] in their analysis of real wages over the business cycle.
6. The multinomial approach to characterising the distribution of heterogeneity has been used in various microeconomic analyses of, for instance, dynamic discrete choice [Moon and Stotsky, 1993; Blau and Gilleskie, 2001], duration data [Blau, 1994; Ham and LaLonde, 1996], and count data [Deb and Trivedi, 1997].
7. Monte Carlo evidence indicates that this approach compares favourably with standard ML correctly assuming a normal distribution, and that it performs much better than ML incorrectly assuming normality [Mroz and Guilkey, 1995; Mroz, 1999].
8. If the underlying distribution is approximated with too few support points, then this is likely to lead to a downward bias in the estimated variances of the random effects. This is obvious in the lower limit: using only one support point, the variance of the random effect will be zero by definition. If the true variance is non-zero, then in moving from one to two support points we should obtain a non-zero variance. Similarly, in moving from two to three support points the estimated variance should increase further if the two-point approximation is too restrictive. In dynamic models downward bias in the variances of the random effects will be associated with upward bias in the coefficients on the lagged dependent variables. Hence it is crucial for our purposes that the distribution of the random effects is approximated with an adequate number of support points.
9. A simple example may illustrate this. Consider a process where y_t depends on y_{t-1} and a random effect z , and define the per-period likelihood contribution as $f(y_t | y_{t-1}, z)$. Since z is unobserved we need to integrate over its distribution in order to formulate the likelihood solely in terms of observable variables. If y_0 for some reason is independent of z , the likelihood unconditional of z is simply $\int \prod_{t=1}^T f(y_t | y_{t-1}, z) dG(z)$. In this case there is no difference compared to the static counterpart of the model. However, if y_0 is dependent of z , say because the process began before the time of the first observation of the sample, the likelihood is equal to $\int \prod_{t=1}^T f(y_t | y_{t-1}, z) h(y_0 | z) dG(z)$, where $h(y_0 | z)$ denotes the marginal

- density of y_0 given z . Dealing with $h(y_0 | z)$ is the initial conditions problem [Hsiao, 1986: 169–172].
10. If the probability of being included in the sample is correlated with unobservable factors affecting the dependent variables in our regressions, it is possible that this introduces selectivity bias. The most direct way to remedy this involves specifying a selectivity model. This would be quite complicated given the nature of the models we estimate in Section IV, and we do not attempt to do so in this paper. Nevertheless, if sample selectivity introduces substantial bias we would expect this to be picked up by our instrumental variable estimates (as selectivity bias is a form of omitted variables bias).
 11. Specifically, we begin by constructing firm specific Laspeyres indices as weighted sums of the consumer price index and an index of the nominal exchange rate to the US dollar. We construct one index for output and one for inputs, using as weights for the output index the percentage of output exported in the initial period, and for inputs the percentage of raw materials imported in the initial period. We then use these indices to deflate output and raw material costs to constant 1992 domestic prices. We deflate physical capital using the nominal exchange rate as physical capital typically is imported and we do not have data enabling us to construct weighted indices. Indirect costs are deflated using the CPI as this input (electricity, water, etc.) typically is not imported. We then convert all monetary variables to PPP adjusted 1992 US dollars, to ensure that the data are comparable across countries.
 12. To translate this into an effect on the probability of exporting, consider a non-exporting firm whose predicted probability of exporting at time t is 0.10. If this firm breaks into the export market at time t then, holding all other characteristics constant, the predicted probability of exporting at time $t+1$ would increase from 0.10 to about 0.77, clearly a large effect.
 13. Increasing the number of support points further resulted in a very small increase in the log likelihood value.
 14. The point estimate of the coefficient on lagged exports is equal to 1.081. If a previously non-exporting firm, whose predicted probability of exporting at time t is 0.10 conditional on observables and the unobserved firm effect, breaks into the export market at time t then, holding all other characteristics constant, the predicted probability of exporting at time $t+1$ would increase from 0.10 to about 0.42. It is noted that this is a much smaller effect than that implied by the results ignoring unobserved heterogeneity, see note 12. This is an example of how ignoring unobserved time invariant heterogeneity in dynamic models leads to ‘spurious state dependence’, Heckman [1981a, 1981b].
 15. Monotonicity requires that each input has a positive marginal product, and quasi-concavity requires that the bordered Hessian matrix of first and second partial derivatives of the production function are negative semi-definite.
 16. It is noted, however, that the translog model complies relatively poorly with monotonicity and quasi-concavity: about 70 per cent of the observations comply with monotonicity, while less than 40 per cent of the observations are consistent with quasi-concavity. It is possible that this is driven by imprecise estimates of the elasticities.
 17. To see this, assume for simplicity that the cost of raw materials and indirect inputs is a constant fraction of output. In this case the long-run coefficients on factor inputs in the output model are scaled up by the inverse of one minus the sum of the long-run coefficients on the intermediate inputs, to yield value-added equation coefficients.
 18. Given that these are value-added production functions, we let value-added per employee and capital per employee represent the self-selection effect in the export probit.
 19. Under the assumption that η_{it} is non-autocorrelated, $y_{i,t-2}$ should be uncorrelated with $\Delta\eta_{it}$ and correlated with $\Delta y_{i,t-1}$ and thus be a potential instrument. Longer lags of the dependent variable would also be potential instruments, however this will not be of use for our purposes since the panel consists only of three periods. Further, under the assumption that the factor inputs are uncorrelated with the residual η_{it} (this assumption is relaxed in the specification reported in Table 5, Column 2), contemporaneous and lagged values of the factor inputs are additional potential instruments.
 20. It is well known that the asymptotic standard errors in two-step GMM estimators can be severely downward biased in finite samples [Arellano and Bond, 1991]. As a consequence,

- researchers often draw inference based on one-step GMM estimators, which are less efficient than the two-step estimators. However, Windmeijer [2000] shows how the asymptotic two-step standard errors can be corrected when the sample size is finite. Monte Carlo evidence reported by Bond and Windmeijer [2001] indicates that this procedure yields a much more reliable basis for inference than relying on the asymptotic standard errors.
21. In some special cases the C-test is numerically identical to the more familiar Durbin-Wu-Hausman test. One advantage of the C-test is that it, unlike the Durbin-Wu-Hausman test, is straightforward to implement in the case of conditional heteroskedasticity. See Chapter 3 in Hayashi [2000] for details.
 22. A similar result has been obtained by Söderbom and Teal [2003], estimating production functions using seven years of panel data on Ghanaian manufacturing firms, so this finding is not an artefact of our sample.
 23. We have also examined the distribution of the firm effects based on the GMM estimates of the production function reported in Table 5, Column 2, which is arguably the least restrictive model reported in the paper as all inputs are assumed endogenous. Based on the point estimates we recover the residuals from equation (1) in levels, regress these on company dummies and take the coefficients on the firm dummies to be estimates of the firm effects (we are indebted to a referee for suggesting this procedure). Consistent with the NPML results the distribution of these firm effects exhibits both right skewness and excess kurtosis, and we can reject normality at the 1 per cent level of significance.
 24. It has long been known in the duration literature, for instance, that models based on parametric assumptions about the hazard function and the heterogeneity distribution can lead to seriously biased results [Heckman and Singer, 1984].
 25. The restriction $\rho_{uv} = 0$ can be rejected at the 5 per cent level of significance, but not at the 1 per cent level.

APPENDIX
LIKELIHOOD FUNCTIONS UNDERLYING THE ML MODELS

Our ML estimators are similar to Keane *et al.* [1998] and Clerides *et al.* [1998]. For notational simplicity, express the production function (1) as

$$y_{it} = z_{1it}b_1 + \mu_i + \eta_{it},$$

and the export equation (2) as

$$x_{it}^* = z_{2it}b_2 + \psi_i + \omega_{it},$$

where

$$x_{it} = \begin{cases} 1 & \text{if } x_{it}^* \geq 0 \\ 0 & \text{if } x_{it}^* \leq 0 \end{cases}$$

is observed. Conditional on μ_i , ψ_i , z_{1it} and z_{2it} , the contribution of firm i to the sample likelihood is equal to

$$L_i = \prod_{t=1}^T \Phi \left((2x_{it} - 1) \cdot (z_{2it}b_2 + \psi_i + (\rho_{\eta\omega}/\sigma_\eta) \cdot (y_{it} - z_{1it} - \mu_i)) \cdot (1 - \rho_{\eta\omega}^2)^{-0.5} \right) \times \sigma_\eta^{-1} \cdot \phi((y_{it} - z_{1it}b_1 - \mu_i)/\sigma_\eta), \quad (\text{A1})$$

where $\Phi(\cdot)$ and $\phi(\cdot)$ are the standard normal distribution and density functions, respectively.

A. No unobserved heterogeneity

No unobserved heterogeneity of the form $\sigma_\mu^2 = \sigma_\psi^2 = \rho_{\mu\psi} = 0$ implies that μ and ψ are constant across firms. In this case the likelihood (A1) can be written

$$L_i = \prod_{t=1}^T \Phi \left((2x_{it} - 1) \cdot (z_{2it}b_2 + (\rho_{\eta\omega}/\sigma_\eta) \cdot (y_{it} - z_{1it}b_1)) \cdot (1 - \rho_{\eta\omega}^2)^{-0.5} \right) \cdot \sigma_\eta^{-1} \cdot \phi((y_{it} - z_{1it}b_1)/\sigma_\eta). \quad (\text{A2})$$

[Clerides *et al.*, 1996, Appendix III]. The sample log likelihood, written as

$$\log L = \sum_i \log L_i(\cdot), \quad (\text{A3})$$

is straightforward to maximise using some iterative method. For all ML results reported in the paper we use the SAS/IML NLPDD subroutine to maximise the log likelihood function.

B. The CLT method

Under the assumption that μ and ψ follow a bivariate normal distribution, we can express the likelihood function conditional on observable data by integrating out μ and ψ . To deal with the initial conditions problem arising from the presence of heterogeneity and dynamics, we follow Heckman's [1981a, 1981b] suggestion of adding equations to the system that model the initial conditions y_{i0} and x_{i0} as functions of exogenous regressors z_{3i0} and z_{4i0} , respectively, and the firm effects:

$$y_{i0} = z_{3i0}b_3 + \tau_3 \cdot \mu_i + \xi_{3i0}$$

$$x_{i0}^* = z_{r i0}b_4 + \tau_4 \cdot \psi_i + \xi_{4i0},$$

where τ_3 and τ_4 are factor loading parameters, and the residuals are normally distributed:

$$(\xi_{3i0}, \xi_{4i0}) \sim N(0, \Lambda), \quad \Lambda = \begin{vmatrix} \sigma_{\xi_{33}}^2 & \\ 0 & 1 \end{vmatrix}.$$

The resulting individual likelihood can be written

$$L_i = \int \int L_i(\cdot | \mu, \psi) dF(\mu, \psi), \tag{A4}$$

where

$$L_i(\cdot | \mu, \psi) = \prod_{t=1}^T \Phi \left((2x_{it} - 1) \cdot (z_{2it}b_2 + \psi + (\rho_{\eta\omega}/\sigma_\eta) \cdot (y_{it} - z_{1it}b_1 - \mu)) \cdot (1 - \rho_{\eta\omega}^2)^{-0.5} \right) \times$$

$$\sigma_\eta^{-1} \cdot \phi((y_{it} - z_{1it}b_1 - \mu)/\sigma_\eta) \cdot \Phi((2x_{i0} - 1) \cdot (z_{4i0}b_4 + \tau_4 \cdot \psi)) \cdot \sigma_{\xi_{33}}^{-1} \times$$

$$\phi((y_{i0} - z_{3i0}b_3 - \tau_3 \cdot \mu)/\sigma_{\xi_{33}}), \tag{A5}$$

and $F(\cdot)$ is the bivariate normal distribution. To solve (A4) we follow CLT and use a bivariate Gauss-Hermite quadrature, which involves expressing μ and ψ as linear combinations of two orthogonal random terms using a Cholesky decomposition, and then integrating over the two orthogonal random terms using standard (univariate) quadrature techniques [Judd, 1998, Chapter 7]. We then maximise the sample log likelihood using the SAS/IML NLPDD subroutine.

C. The NPML Model

The discrete, multinomial equivalent of the CLT individual likelihood function (A4) is equal to

$$L_i = \sum_{q=1}^Q \sum_{r=1}^R P_{qr} L_i(\cdot | \mu = \mu_q, \psi = \psi_r), \tag{A6}$$

where

$$L_i(\cdot | \mu = \mu_q, \psi = \psi_r) =$$

$$\prod_{t=1}^T \Phi \left((2x_{it} - 1) \cdot (z_{2it}b_2 + \psi_r + (\rho_{\eta\omega}/\sigma_\eta) \cdot (y_{it} - z_{1it}b_1 - \mu_q)) \times (1 - \rho_{\eta\omega}^2)^{-0.5} \right)$$

$$\cdot \sigma_\eta^{-1} \cdot \phi((y_{it} - z_{1it}b_1 - \mu_q)/\sigma_\eta) \times \Phi((2x_{i0} - 1) \cdot (z_{4i0}b_4 + \tau_4 \cdot \psi_r)) \cdot \sigma_{\xi_{33}}^{-1} \times$$

$$\phi((y_{i0} - z_{3i0}b_3 - \tau_3 \cdot \mu_q)/\sigma_{\xi_{33}}), \tag{A7}$$

and

$$\sum_{q=1}^Q \sum_{r=1}^R P_{qr} = 1, \quad P_{qr} \geq 0 \text{ for all } q, r.$$

The restrictions on the probability terms are imposed by specifying appropriate boundary and linear equality constraints in the computer code. Some trivial normalisations are also necessary [Mroz, 1999]. Because we include intercepts in each equation only $Q-1$ and $R-1$ support points are identified. Following Blau [1994] we parameterise the support points as $\mu_q = \Gamma_\mu \cdot W_{\mu q}$ and $\psi_r = \Gamma_\psi \cdot W_{\psi r}$, where Γ_μ and Γ_ψ are scale factors and

$$W_{\mu q} = \begin{cases} -0.5 & \text{if } q = 1 \\ 0.5 - (1 + \exp(-a_{\mu q}))^{-1} & \text{if } 1 < q < Q \\ 0.5 & \text{if } q = Q \end{cases},$$

$$W_{\psi r} = \begin{cases} -0.5 & \text{if } r = 1 \\ 0.5 - (1 + \exp(-a_{\psi r}))^{-1} & \text{if } 1 < r < R \\ 0.5 & \text{if } r = R \end{cases}.$$

The sample log likelihood is maximised using the SAS/IML NLPDD subroutine. The estimation exercise is quite costly, since convergence is slow and may occur at a local optimum. To guard against convergence at local points we adopt a 'brute force' multiple step procedure, suggested by Thomas Mroz in a personal communication. The first step is to take 50 bootstrap samples from the original sample, assign random start values, carry out 15 iterations from the random start values for each sample and store the resulting estimates. We proceed by using the original sample and carry out 15 iterations using each of the 50 estimates as start values. We then select the 25 parameter vectors associated with the highest log likelihood values, and try to bring each one to an optimum. The one with the highest function value is taken to be the maximum likelihood estimator. We experimented with increasing the number of bootstrap samples as well as the number of intermediate iterations, but found the above numbers to be adequate.
